Problem Solving, Programming, and Calculation (revised 2015-04-12)

Computation by Calculation

In "ordinary" programming languages, computation alters state by writing new values to program variables:

```
State before: x = 3, y = 4

x = 17 + x + y

State after: x = 24, y = 4
```

This means you perform computations in sequence

There is a *control flow* that decides this sequence:

```
for(i=0,i++,i<17)
    { if (j > i) then x++ else y++;
       x = y + j;
}
```

Overview

Basic concepts of functional programming: computation by calculation, values, expressions, types, declarations

First glance of F#: introduction, basic language elements

Some simple functional programming examples/exercises

Problem Solving, Programming, and Calculation (revised 2015-04-12)

In (pure) functional languages, computation is simply *calculation*:

$$3*(9+5) \implies 3*14$$

Forget about assignments, sequencing, loops, if-then-else, ...

Forget everything you know about programming! (Well, almost)

You might wonder how to do useful stuff just by calculating, we'll see later . . .

In functional languages we have:

- functions
- recursion (instead of loops)
- expressive data types (much more than numbers)
- advanced data structures

and calculation on top of that

Problem Solving, Programming, and Calculation (revised 2015-04-12)

Defining a function by writing all pairs can be very tedious

Often defined by simple rules instead

$$simple(x, y, z) = x \cdot (y + z)$$

These rules express *abstraction*: that a similar pattern holds for many different inputs

("For all
$$x, y, z$$
, $simple(x, y, z)$ equals $x \cdot (y + z)$ ")

Abstraction makes definitions shorter and easier to grasp

A good property also for software, right?

Functions

Functions, mathematically: sets of pairs where no two pairs can have the same first component:

$$f = \{(1,17), (2,32), (3,4711)\}$$
$$f(2) = 32$$

Or, given the same argument the function always returns the same value (cannot have f(2)=32 and f(2)=33 at the same time)

Functions model *determinism*: that outputs depend predictably on inputs Something we want to hold for computers as well . . .

Problem Solving, Programming, and Calculation (revised 2015-04-12)

-

Recursion

Mathematical functions are often specified by recursive rules

Recursion means that a defined entity refers to itself in the definition

This seems circular, but can make sense

Example: the factorial function "!" on natural numbers

$$0! = 1$$

$$n! = n \cdot (n-1)!, \quad n > 0$$

Recursion corresponds to loops in ordinary programming

Pure Functional Languages

Pure functional languages implement mathematical functions

A functional language is pure if there are no *side-effects*

A side effect means that a function call does something more than just return a value

An example in C:

```
int f(int x)
 n++;
 return(n+x);
```

Problem Solving, Programming, and Calculation (revised 2015-04-12)

In pure functional languages, functions are specified by side-effect free rules (declarations)

In F#:

let simple x y z =
$$x*(y + z)$$

Each rule defines a calculation for any actual arguments:

simple 3 9 5
$$\implies$$
 3*(9 + 5)
 \implies 3*14
 \implies 42

Just put actual arguments into the right-hand side and go!

Compare this with an execution model that must account for side-effects

Side effect for f: global variable n is incremented for each call

This means that f returns different values for different calls, even when called with the same argument

Much harder to reason mathematically about such functions: for instance,

$$f(17) + f(17) \neq 2*f(17)$$

Side effects requires a more complex model, and thus makes it harder to understand the software

Problem Solving, Programming, and Calculation (revised 2015-04-12)

Exercise

Calculate simple (simple 2 3 4) 5 6

Note that we can do the calculation in different order

Do we get the same result?

More on this later ...

10

The mathematical view makes it possible to *prove* properties of programs When calculating, all intermediate results are *mathematically equal*:

simple 3 9 5 =
$$3*(9 + 5) = 3*14 = 42$$

For instance, prove that simple x y z = simple x z y for all x, y, z:

simple x y z =
$$x*(y + z)$$

= $x*(z + y)$
= simple x z y

We cannot do this for functions with side-effects

Problem Solving, Programming, and Calculation (revised 2015-04-12)

Types

Many programming languages have types

Types represent sets of values (like integers)

Types help avoiding certain programming errors, like adding an integer with a character

A programming language can be:

- strongly typed: every program part must have a legal type
- weakly typed: every program part can have a legal type, but need not
- untyped: no types exist

Expressions, Values, and Types

Calculation is performed on expressions:

```
simple (simple 2 3 4) 5 6
```

Expressions are calculated into *values*:

```
simple (simple 2 3 4) 5 6 \Longrightarrow 154
```

Values are also expressions, which cannot be calculated any further

Problem Solving, Programming, and Calculation (revised 2015-04-12)

13

A First Introduction of F#

F# is a strongly typed, functional language

It uses *eager evaluation* (compute function arguments fully before making the call), but also supports *lazy evaluation* and *computation by demand* (don't compute anything before it's needed)

It is *higher order* (functions are ordinary data)

It is *not pure* (side effects possible), but encourages pure programming

It supports imperative and object-oriented programming

It has a *polymorphic* type system, with *type inference*, *subtyping*, and *overloading* of common operators

It has syntactic facilities to help write clear and understandable programs

F# implementation

F# comes from Microsoft Research

Current version is 3.1 (the lab computers have 2.0)

Included in VS 2012, can also be freely downloaded

Can also be run on Mac/linux under Mono v. 3.0 or later (F# 3.1)

Three ways to run F# compiler:

- In Visual Studio
- fsc (v. 2.0) or fsharpc (v. 3.1) batch compiler
- fsi (v. 2.0) or fsharp1 (v. 3.1) interactive command line compiler

Problem Solving, Programming, and Calculation (revised 2015-04-12)

16

Numerical Types

F# has a number of numerical types, some important examples:

```
int
          32-bit integers (1, -3, 54873, ...)
          double precision (64-bit) floats (1.0, 3.14159, 3.2e3, ...)
float
          64-bit integers (1L, -3L, 54873L, ...)
int64
          single precision (32-bit) floats (1.0f, 3.14159f, 3.2e3f, ...)
```

Basic Language Elements of F#

A first introduction:

- Values
- Types (atomic values, composed values)
- Operators and predefined functions
- Other syntactic forms

Problem Solving, Programming, and Calculation (revised 2015-04-12)

17

Functions and Operators on Numerical Types

The usual ones:

```
+, -, *, /, % (modulus): all numeric types
```

Operands must have same type: 2 + 3 OK, 2 + 3.0 not OK

** (power): all floating-point types

Bitwise operators: all integer types

Most "typical" math functions (trigonometric, exponent, etc)

Type conversion functions: same name as type converted to:

int 17.3
$$\Longrightarrow$$
 17

int
$$17L \implies 17$$

Numerical Expressions

Characters

Numerical expressions look like in most languages:

$$3.14159/(x + 1.0) - 33.0$$

(x + 7*y is the same as x + (7*y), since *binds stronger than +)

Problem Solving, Programming, and Calculation (revised 2015-04-12)

Problem Solving, Programming, and Calculation (revised 2015-04-12)

Syntax: 'a', 'b', '\n' (newline), ...)

Characters are elements in *strings*

Type char for characters

More on strings later

Booleans

Type bool for the two booleans values true, false

Boolean operators and functions: & & (and), | | (or), not

Relational operator returning a boolean value: =, <>, <, <=, >=, >

Can compare elements from any "comparable" type (more on this later)

Conditional

F# has a conditional if-then-else expression:

if true then x else $y \implies x$

if false then x else $y \implies y$

So we can write expressions like

if x > 0 then x else -x

However, the two branches must have the same type

Thus, if x > 0 then 17 else 'a' is illegal

21

Functions

Functions take a number of arguments and return a result

Some predefined ones, and you can define your own

A little unusual syntax: no parentheses around arguments

sgrt 17.0

exp 17.0 3.0

(There are good reasons for this syntax, more on this later)

Problem Solving, Programming, and Calculation (revised 2015-04-12)

Problem Solving, Programming, and Calculation (revised 2015-04-12)

(Common beginner's mistake to forget this)

operator: function application

25

Declarations

You can define your own entities

Entities of any type can be defined by a let declaration

let pi = 3.14159 defines pi to be a floating-point constant

let simple x y z = x*(y+z) defines simple to be a function in three arguments

Types of Defined Entities

The space between function and argument can be seen as a special

Function application binds harder than any other operator

Thus, f x + y means (f x) + y, not f (x + y)

Note that we did not give any types in the definitions

F# manages to find types automatically!

This is called *type inference*

A very simple example:

let pi = 3.14159

Here, pi will automatically obtain the type float since 3.14159 can only have type float

Explicit Type Declarations

However, we can also give explicit types (sometimes useful)

e: t declares e to have type t

For instance:

let f x = (x + x): float forces the right-hand side of the declaration to have type float.

(If we just write let f x = (x + x), then F# will assume that "+" is plus on the type int.)

What about let f x = (x + x): char?

Problem Solving, Programming, and Calculation (revised 2015-04-12)

Factorial in F#

```
let rec fac n = if n = 0 then 1 else n*fac (n-1)
```

Note let rec: recursive definition, fac in right-hand side must be same as in left-hand side. More in this later

Exercise:

Calculate fac 3

Recursive Definitions

As a first exercise, recall the factorial function:

```
0! = 1
n! = n \cdot (n-1)!, \quad n > 0
```

Define it in F#!

(Answer on next slide)

Problem Solving, Programming, and Calculation (revised 2015-04-12)

```
fac 3 \Longrightarrow \text{if } 3 = 0 \text{ then } 1 \text{ else } 3 \star \text{fac } (3-1)
       \implies if false then 1 else 3*fac (3-1)
       \implies 3*fac (3-1)
       \implies 3*fac 2
       \implies 3*(if 2 = 0 then 1 else 2*fac (2-1))
       \implies 3*(if false then 1 else 2*fac (2-1))
       \implies 3*2*fac (2-1)
       ...etc...
       \implies 3*2*1*fac (1-1)
       \implies 3*2*1*fac 0
       \implies 3*2*1*1
       \implies 6
```

Eventually we'll reach the "base case" fac 0. This is what makes recursion work here!

Pattern Matching

Another way to write the factorial function: use *patterns*

F# has a case construct

```
match expr with
      | pattern1 -> expr1
      | pattern2 -> expr2
```

Every case has a *pattern* for the argument

Cases are checked in order, the first that matches the argument is selected

For "atomic" types like numeric types, the possible patterns are constants (matching exactly that constant), or variables (matching any value)

Problem Solving, Programming, and Calculation (revised 2015-04-12)

32

More on Pattern Matching

Note that match ... with is just another expression, it is evaluated and returns a result

Pattern matching is really useful with structured data, where it can be used to conventiently pick out parts of data structures. More on this later

So we can define fac like this instead:

```
let rec fac n = match n with
                  1 0 -> 1
                  | \rightarrow n*fac (n-1)
```

If n is 0 return 0, otherwise return n*fac (n-1)

" " is a "wildcard", matches anything

Problem Solving, Programming, and Calculation (revised 2015-04-12)

Nontermination and Errors

Now what about fac (-1)?

```
fac(-1) \implies (-1) * fac(-2) \implies (-1) * (-2) * fac(-3) \implies \cdots
```

Infinite recursion! Will never terminate.

For computations that never return anything, we use the notation "\perp " for the "resulting value"

```
Thus, fac (-1) = \bot
```

Remember fac is really just defined for natural numbers, not for negative numbers

It's good practice to have controlled error handling of out-of-range arguments

The F# failwith Function

F# has an failwith function, which when executed prints a string and stops the execution

E.g.,

failwith "You cannot input this number to this function" (Strings in F# are written within quotes, like "Hello world")

Problem Solving, Programming, and Calculation (revised 2015-04-12)

Accumulating Arguments

Another way to define the factorial function in F#:

```
let rec fac1 acc n = match n with
                        | 0 -> acc
                        \mid \_ \rightarrow fac1 (n*acc) (n-1)
let fac n = fac1 1 n
```

This solution uses a help function fac1 with two arguments

The second argument is an accumulating argument, where we successively collect the result

Exercise: calculate fac 3 with this new definition

A version of fac with error handling:

```
let rec fac n =
  match n with
  | 0 -> 1
  | -> if n > 0
         then n*fac (n-1)
         else failwith "Negative argument to fac"
```

Would we be able to write this case-by case (n > 0, n = 0, n < 0)?

Yes, pattern-matching can be extended with guards. More on this later

Problem Solving, Programming, and Calculation (revised 2015-04-12)

37

Note similarity with a loop with two variables:

```
acc = 1;
while (n = 0)
  acc = n*acc;
  n = n-1;
return(acc);
```

Local Definitions

The fac version with accumulating argument uses a help function fac1

This function is globally defined

However, only used by fac

We may want to hide it in the definition of fac

F# has a let (rec) ... in ...-construct for *local* definitions:

```
fac n = let rec fac1 acc n = match n with
                               | 0 -> acc
                               \rightarrow fac1 (n*acc) (n-1)
        in fac1 1 n
```

Defines fac1 locally in the expression after "in". Not visible outside!

Problem Solving, Programming, and Calculation (revised 2015-04-12)

42

Function Types

A function that takes an argument of type a and returns a value of type b has the function type a -> b

```
For instance, fac : int -> int
```

(Note resemblance with mathematical notation)

What about functions with several arguments?

```
let simple x y z = x*(y+z)
simple : int -> int -> int -> int
```

Last type is result type, preceding types are the respective argument types (We'll explain later why multi-argument function types look this way)

let (rec) ... in-expressions are ordinary expressions and return values, can be used wherever ordinary expressions can be used:

```
17 + let x = fac 3 in x + 3*x \Longrightarrow
17 + let x = 6 in x + 3*x \implies 17 + (6 + 3*6) \implies 41
```

Also note that the defined entity (x here) only needs to be computed once – saves work!

So let can be used also to save work when the same result is to be used many times

Problem Solving, Programming, and Calculation (revised 2015-04-12)

Types for Data Structures

F# has two important predefined types for data structures: *tuples* and *lists*

(Also some more types for this, but we'll leave them for now)

Lists are very important data structures in functional programming

They are sequences of elements

Lists can be arbitrarily long, but (in F#) all elements must be of the same type If a is a type, then a list is the type "list of a"

E.g. int list, char list, (int list) list,

```
(float -> int) list
```

A list can contain elements of *any* type (as long as all have the same type)

Constructing Lists

Lists are built from:

• the *empty list*: []

• the "cons" operator, which puts an element in front of a list: ::

Example: 1:: (2:: (3::[]))

:: and [] are called *constructors*: they "construct" data structures

(Constants like 17 and $'\,x'$ are also constructors, but they only construct themselves)

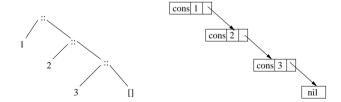

(Don't mix up with constructors in object-oriented langages)

Problem Solving, Programming, and Calculation (revised 2015-04-12)

4

46

To the left is a graphical picture of [1;2;3] as an expression tree:

Underneath, there is a linked data structure (shown to the right)

In conventional languages you'd have to manage the links yourselves. Functional programming runtime systems handle them automatically

```
1::2::3::[] is same as 1::(2::(3::[])) ("::" is right-associative)
[1;2;3] is another shorthand for 1::(2::(3::[]))
```

The first element of a nonempty list is the *head*:

```
List.head [1;2;3] \implies 1
```

(List.head is a function from the $\it List module$, thus the prefix List. More on modules later)

The list of the remaining elements is the tail

List.tail
$$[1;2;3] \Longrightarrow [2;3]$$

Problem Solving, Programming, and Calculation (revised 2015-04-12)

1

Some List Functions

F# has many builtin functions on lists in the ${\tt List}$ module. Let's look at some and try to program them, as an exercise

```
List.length xs, computes the length of the list xs
```

List.length ['a';'b';'c']
$$\Longrightarrow$$
 3

List.sum
$$[1;2;3] \implies 6$$

(Solutions on next slide)

Note the pattern-matching!

The pattern (x::xs) matches any list that is constructed with a cons (that is, any non-empty list)

x gets bound to the head, and xs to the tail

Problem Solving, Programming, and Calculation (revised 2015-04-12)

sum basically replaces :: with + and then calculates the result

This is a common pattern! We'll get back to this when we treat higher-order functions

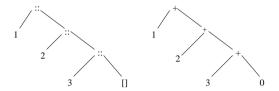

Also: in a sense, data structures (like lists) in F# are just expressions where the "operators" (= constructors) cannot be calculated: thus, the constructors are left in the result (where they build the data structure)

An Observation on Sum

We have:

$$sum [1,2,3] = sum 1::(2::(3::[])) \implies 1+(2+(3+0)) \implies 6$$

Note the similarity between tree for list 1::(2::(3::[])) and sum expression for 1+(2+(3+0)):

Problem Solving, Programming, and Calculation (revised 2015-04-12)

Tuples

Tuples are similar to records, or objects

A tuple is like a container for data with a fixed number of slots

An example: ('a',17,3.14159)

This is a three-tuple whose first component is a character, the second an integer, and the third a floating-point number

It has the *tuple type* char * int * float

Tuples can contain *any* type of data, for instance:

$$(fac, (17, 'x')) : (int -> int) * (int * char)$$

Thus, there are really infinitely many tuple types

An Example of the Use of Tuples

Use tuples with two floats to represent 2D-vectors

Define functions vadd, vsub, vlen to add, subtract, and compute the length of vectors:

```
vadd,vsub : (float * float) -> (float * float) -> (float * float)
vlen : (float * float) -> float
```

(Solutions on next slide)

Problem Solving, Programming, and Calculation (revised 2015-04-12)

Problem Solving, Programming, and Calculation (revised 2015-04-12)

53

Another Matching Example with Tuples

take n xs, returns list of first n elements from the list xs

```
take 2 ['a';'b';'c'] \Longrightarrow ['a';'b']
```

Let's define it using the match ... with construct!

(Solution on next slide)

```
let vadd (x1,y1) (x2,y2) = (x1+x2,y1+y2) : float * float
let vsub (x1,y1) (x2,y2) = (x1-x2,y1-y2) : float * float
let vlen (x,y) = sqrt (x*x + y*y): float
```

Note the pattern-matching to get the components of the argument tuples (Why did we have to type the function bodies?)

```
let rec take n xs =
   match (n,xs) with
   | (0,_) -> []
   (_,[]) -> failwith "taking too many elements"
```

| (,x::xs) -> x :: take (n-1) xs

Note how we constructed a tuple just to be able to match on both arguments to take

The second, "local" xs "obscures" the "outer" xs in the recursive call take (n-1) xs

Excercise: provide some error handling for the case n < 0!
